

Calibration and Model Discrepancy

Tony O'Hagan, MUCM, Sheffield

Outline

- ▶ Why model discrepancy
- ▶ The meaning of parameters
- ▶ Modelling discrepancy
- ▶ Conclusions

Why model discrepancy

Is calibration even possible?

The calibration problem

- ▶ **The problem**
 - ▶ We have a simulator that predicts a real world phenomenon
 - ▶ We have some observations of the real world
 - ▶ We want to use those to learn about some unknown parameters
- ▶ **Formally, the simulator takes two kinds of inputs**
 - ▶ The calibration parameters θ
 - ▶ Control inputs x
 - ▶ Simulator is written $y = f(x, \theta)$
 - ▶ Observation z_i is obtained at control input values x_i

Traditional formulation

- ▶ Write

$$z_i = f(x_i, \theta) + \varepsilon_i$$

- ▶ where ε_i are independent observation errors

- ▶ Estimate θ , e.g. by minimising sum of squared residuals

- ▶ Call estimate t and predict real world process at a new x value by $f(x, t)$

- ▶ Two things wrong with this

- ▶ The formulation is wrong because the simulation model is inevitably wrong

- ▶ So errors are not independent

- ▶ Traditional calibration ignores uncertainty about θ

- ▶ Treats it as now known to equal t

Little example

- ▶ **One control input, one calibration parameter**
 - ▶ Three observations marked with crosses
 - ▶ Red lines are possible simulator outputs
 - ▶ Calibration parameter just changes slope of line
- ▶ **No value of the calibration parameter gets close to all the observations**
 - ▶ And yet they seem to lie on a straight line

Is calibration even possible?

- ▶ **Green line is best fit**
 - ▶ Minimises sum of squared residuals
 - ▶ Red line seems better
 - ▶ But with constant bias
 - ▶ Green seems to be over-fitting
 - ▶ Errors don't look independent
- ▶ **Can we learn the true value of the calibration parameter?**
 - ▶ With more data
 - ▶ Keeping close to a straight line
 - ▶ Over a different range of x

Model discrepancy

- ▶ The little example suggests that we need to allow that the model does not correctly represent reality
 - ▶ For *any* values of the calibration parameters
- ▶ The simulator outputs deviate systematically from reality
 - ▶ Call it model bias or model discrepancy
- ▶ It is claimed that acknowledging model discrepancy may allow us to achieve more realistic and appropriate estimates of calibration parameters
- ▶ But to evaluate that claim, look at a simpler problem

The meaning of parameters

What can we learn from simple models?

What do parameters mean?

- ▶ All models are wrong
 - ▶ “All models are wrong but some are useful”
 - ▶ George E P Box, 1979
- ▶ So, what does a parameter (in an admittedly wrong model) mean?
 - ▶ How do we specify prior information about a parameter
 - ▶ when we know the model is wrong?
 - ▶ What have we learnt when we make inference about a parameter
 - ▶ in a model we know to be wrong?

Example: Poisson sample

- ▶ Suppose we model data as a sample from a Poisson distribution with parameter λ
- ▶ We need a prior distribution
 - ▶ Do we ask for beliefs about the population mean or variance?
 - ▶ Or about the proportion p of zeros in the population?
 - ▶ And infer a prior for $\lambda = -\log p$
 - ▶ Given that the Poisson assumption is wrong these are all asking about different things
- ▶ When we derive a posterior distribution for λ
 - ▶ Is it a belief statement about the population mean or variance?
 - ▶ Or even about anything real?

Example: Linear regression

- ▶ Suppose we assume a simple linear regression model with slope β and intercept α
 - ▶ We are interested in the strength of the relationship as represented by β
 - ▶ But the model is wrong; the relationship is not truly linear
- ▶ We know if we switch to a quadratic model the coefficient of x will change
 - ▶ If we assume a linear relationship when the truth is different, e.g. quadratic, the slope will depend on the range of x over which we fit
 - ▶ How can we elicit prior beliefs about such a parameter?
 - ▶ What do inferences about it mean?

Example: A simple machine

- ▶ A machine produces an amount of work y which depends on the amount of effort t put into it
 - ▶ Model is $y = \beta t + \varepsilon$
 - ▶ Where β is the rate at which effort is converted to work
 - ▶ And ε is observation error, assumed iid
 - ▶ True value of β is 0.65
- ▶ Graph shows observed data
 - ▶ All points lie below $y = 0.65t$
 - ▶ Because the model is wrong
 - ▶ Losses due to friction etc.
 - ▶ Fitted slope is 0.568

Figure 1

Simple machine – true model

- ▶ The true model is shown as the dashed line here
- ▶ In this example, the efficiency parameter β is physically meaningful
 - ▶ Theoretical value is 0.65
 - ▶ This value is of interest to experimenters
 - ▶ They have genuine prior information
 - ▶ They want the experiment to help them identify this true value
 - ▶ But because of model error the estimate is biased
 - ▶ And given enough data it will over-rule any prior information

Figure 2

Calibration is just nonlinear regression

- ▶ Returning to the context of computer models

$$y = f(\mathbf{x}, \theta) + \varepsilon$$

- ▶ where f is a computer simulator of some phenomenon
- ▶ We can view this as just a nonlinear regression model
 - ▶ The regression function $f(\mathbf{x}, \theta)$ is complex and we can't try alternatives (as we would do in regression modelling)
 - ▶ But we have all the same problems as in simple regression
- ▶ Given that the model is wrong:
 - ▶ What do the calibration parameters θ mean?
 - ▶ We can't expect to learn their 'true' values from observations
 - ▶ Even with unlimited data

Tuning and physical parameters

- ▶ Simulator parameters may be physical or just for tuning
- ▶ We adjust tuning parameters so the model fits reality better
 - ▶ We are not really interested in their 'true' values
 - ▶ We calibrate tuning parameters for prediction
- ▶ Physical parameters are different
 - ▶ We are often really interested in true physical values
 - ▶ And we like to think that calibration can help us learn about them
 - ▶ But the model is inevitably wrong, so estimates are distorted
 - ▶ And getting more data does not take us closer to their true values
 - ▶ Calibration to learn about physical parameters is a delusion
 - ▶ Unless ... ?

Modelling discrepancy

Is model discrepancy the answer?

Model discrepancy

- ▶ In the context of computer models, it is necessary to acknowledge model discrepancy
 - ▶ There is a difference between the model with best/true parameter values and reality
$$y = f(\mathbf{x}, \theta) + \delta(\mathbf{x}) + \varepsilon$$
 - ▶ where $\delta(\mathbf{x})$ accounts for this discrepancy
 - ▶ Will typically itself have uncertain parameters
- ▶ Kennedy and O'Hagan (JRSSB, 2001) introduced this model discrepancy
 - ▶ Modelled it as a zero-mean Gaussian process
 - ▶ They claimed it acknowledges additional uncertainty
 - ▶ And mitigates against over-fitting of θ

Simple machine revisited

- ▶ So add this model discrepancy term to the linear model of the simple machine

$$y = \beta t + \delta(t) + \varepsilon$$

- ▶ With $\delta(t)$ modelled as a zero-mean GP
 - ▶ As in Kennedy and O'Hagan
- ▶ Now the estimate of β is 0.518
 - ▶ It's even further from the true value of 0.65!
 - ▶ Without model discrepancy we got 0.568
- ▶ What's going on?

- ▶ In order to get the right answer we have to infer:
 - ▶ The true value of the efficiency parameter is 0.65
 - ▶ The solid line
 - ▶ Model discrepancy is negative for all t
 - ▶ And more so for larger t
 - ▶ Like the black curve below
- ▶ But the GP says:
 - ▶ It's much more likely to be the green curve

Nonidentifiability

- ▶ Formulation with model discrepancy is not identifiable
- ▶ For any θ , there is a $\delta(\mathbf{x})$
 - ▶ Reality is some function $\zeta(\mathbf{x}) = f(\mathbf{x}, \theta) + \delta(\mathbf{x})$
 - ▶ Given θ , model discrepancy is $\delta(\mathbf{x}) = \zeta(\mathbf{x}) - f(\mathbf{x}, \theta)$
 - ▶ As in the three curves in the previous example
- ▶ Suppose we had an unlimited number of observations
 - ▶ We would learn reality's true function $\zeta(\mathbf{x})$ exactly
 - ▶ But we would still not learn θ
 - ▶ It could in principle be anything
 - ▶ In a Bayesian analysis, the prior distribution is used to resolve nonidentifiability

The joint posterior

- ▶ Calibration leads to a joint posterior distribution for θ and $\delta(\mathbf{x})$
- ▶ But nonidentifiability means there are many equally good fits $(\theta, \delta(\mathbf{x}))$ to the data
 - ▶ Induces strong correlation between θ and $\delta(\mathbf{x})$
 - ▶ This may be compounded by the fact that simulators often have large numbers of parameters
 - ▶ (Near-)redundancy means that different θ values produce (almost) identical predictions
 - ▶ Sometimes called equifinality
- ▶ Within this set, the prior distributions for θ and $\delta(\mathbf{x})$ count

Modelling the discrepancy

- ▶ The nonparametric GP term allows the model to fit and predict reality accurately given enough data
- ▶ But it **doesn't** mean physical parameters are correctly estimated
 - ▶ The separation between original model and discrepancy is unidentified
 - ▶ Estimates depend on prior information
 - ▶ Unless the real model discrepancy is just the kind expected a priori the physical parameter estimates will still be biased
- ▶ It is necessary to **think** about the model discrepancy
 - ▶ In the machine example, a prior distribution saying $\delta(t)$ is likely to be negative and decreasing will produce a better answer

What do I mean by ‘better’?

- ▶ Posterior distribution for θ will typically be quite wide
 - ▶ And won't become degenerate with infinite data
- ▶ Values of θ with very low posterior probability will typically either
 - ▶ Have very low prior probability or
 - ▶ Imply a $\delta(x)$ with very low prior probability
- ▶ Assuming we don't get prior information about θ wrong, it's important to model $\delta(x)$ carefully
 - ▶ Flexibly but informatively
- ▶ So ‘better’ means getting a posterior distribution that covers the true θ

Reification

- ▶ In the computer models context, Goldstein and Rougier (JSPI, 2009) introduced a formal mechanism for modelling model discrepancy
 - ▶ Called reification
- ▶ Based on imagining hypothetical improved model(s)
 - ▶ The reified model is such that we have no knowledge of how it might differ from reality,
 - ▶ So homogeneous zero-mean discrepancy is appropriate
 - ▶ We may also be able to consider the next-generation model in which specific improvements have been made
- ▶ Their framework may be over-kill, but
 - ▶ if we want parameters to have meaning we have to think seriously about model discrepancy

Extrapolation

- ▶ Here's an example of how important discrepancy modelling is
- ▶ Consider prediction using a regression model but for x values far from the data
 - ▶ We often hear how extrapolation is a bad idea, because of model discrepancy
 - ▶ But if $\delta(x)$ has finite variance the impact is bounded, no matter how far we extrapolate
 - ▶ For unbounded impact in large extrapolations we could model discrepancy using something like a random walk
 - ▶ Or a localised regression model (O'Hagan, JRSSB, 1978)

Conclusions

And challenges!

Key messages

- ▶ If you don't include some representation of model discrepancy, you can expect to get nonsense
 - ▶ Posterior distribution of θ will converge to wrong value
 - ▶ Overfitting and spurious accuracy
- ▶ Even if you do include model discrepancy, it's essential to **think** about it and model it carefully
 - ▶ Use knowledge about aspects of reality that are not adequately represented in the model
- ▶ Even if you do think about it and model it carefully,
 - ▶ You will not be able to learn the true physical values of calibration parameters
 - ▶ Not even with an unlimited number of physical observations
 - ▶ Posterior distribution of θ will not converge
 - ▶ But should cover the true value

Challenges

- ▶ We need to gain much more practical experience of how calibration works when we incorporate model discrepancy
- ▶ A major challenge is how to model the discrepancy
 - ▶ ‘Flexibly but informatively’
